Abstract

Purpose—Bone transport distraction osteogenesis (BTDO) provides a promising alternative to traditional grafting techniques. However, existing BTDO devices have many limitations. The purpose of this research was to test a new device, the mandibular bone transport reconstruction plate (BTRP), in an animal model with comparable mandible size to humans and to histologically and mechanically examine the regenerate bone.

Materials and methods—Eleven adult foxhound dogs were divided into an unreconstructed control group of 5 animals, and an experimental group of 6 animals. In each animal, a 34 mm segmental defect was created in the mandible. The defect was reconstructed with BTRP. Histological and biomechanical characteristics of the regenerate and un-repaired defect were analyzed and compared to bone on the contralateral side of the mandible after 4 weeks of consolidation.

Results—The reconstructed defect was bridged with new bone, with little bone in the control defect. Regenerate density and microhardness were 22.3% and 42.6% lower than the contralateral normal bone, respectively. Likewise, the anisotropy of the experimental group was statistically lower than in the contralateral bone. Half the experimental animals showed non-union at the docking site.

Conclusion—The device was very stable and easy to install and activate. After one month of consolidation, the defect has been bridged with new bone with evidence of active bone formation. Regenerate bone was less mature than the control bone. Studies are underway to identify when the...
regenerate properties compare to normal bone, and to identify methods to augment bone union at the docking site.

**Introduction**
Segmental defects of the mandibular bone are difficult to reconstruct. These defects may result from trauma, benign and malignant tumor resections, and infections. Consequences, include facial deformities, impaired masticatory performance, lip incompetence, poor speech functions, and impaired deglutition.[1]

Bone transport distraction osteogenesis (BTDO) is a method of bone defect reconstruction that has been used in the long bones for decades. Using the principles of distraction osteogenesis, BTDO works by creating an osteotomy by detaching a bone segment (transport disc) from one end of the defect and moving it gradually across the gap to the other end. As the bone segment is moved, bone should form behind it, filling the defect. The new bone should have similar quality and physical dimensions to the original bone.[2]

Several bone transport distraction devices are available for mandibular reconstruction, with very promising results. Some of these devices can be applied extraorally through transcutaneous pins,[3-5] while others are buried under the mucosa.[6-11] However, current devices have many limitations that mitigate their use on a wide scale.

In a canine segmental mandibular defect model, we have tested a new intraoral bone transport device, the bone transport reconstruction plate (BTRP).[12] In this device, the reconstruction plate itself functioned as the transport track, eliminating the need to have a super-imposed device that carries the transport track.. This has remarkably reduced the size of the device and facilitated its installation, activation and adjustment procedures. It also allowed for staging the procedure, since the device can be retained for a long time with minimal discomfort to the patient. It will also make it possible to cross the midline in case of anterior mandibular defects, since it could be retained for prolonged periods under the mucosa. In the present study, we analyzed the histological and biomechanical parameters of the new bone created within a unilateral segmental mandibular defect, compared to the normal bone of the contralateral side of the mandible. The advantages, disadvantages, and limitations of the device and technique are also emphasized.

**Materials and Methods**
**Animals**
Eleven adult foxhound dogs weighting 81.5 ± 8.3 pounds were divided into an untreated control group of 5 animals, and an experimental group of 6 animals. In both groups, a unilateral segmental defect of 33.8 ± 8.4 mm length was created. Each defect was stabilized by the plate portion of the Bone Transport Reconstruction Plate (BTRP; Craniotech ACR Devices, LLC, Dallas, TX) (Fig 1). In the experimental group, the transport unit of the device was installed on the plate and the defect was reconstructed by BTRP. In the control group, the defect was not reconstructed further. At autopsy, the mandibles were collected and the devices were removed. Bone regenerates were harvested, fixed, and processed for undecalcified histology sections. Bone mechanical properties were tested in the regenerate.
using microindentation and ultrasound. Comparisons were made between the bone regenerate and the contralateral (non-operated) side of the mandible.

The untreated control animals were used to confirm the size of the defect as a critical-sized defect in this model. Based on previous experience with critical-size defect models, an untreated control group was necessary to confirm that a similar size defect would not heal spontaneously with the duration and method of bone fixation and housing and nutritional conditions of the experimental animals. The housing, care, and experimental protocol were in accordance with the guidelines set forth by the Baylor College of Dentistry Institutional Animal Care and Use Committee.

Device and Surgical Protocol

Preoperatively, the mandibular canine tooth on the surgical side had root-canal treatment in anticipation of root injury by the fixation screws. The maxillary third and fourth pre-molars and the first molar on the same side of the defect were extracted to eliminate occlusal trauma to the mucosa covering the defect zone.

Device description, installation and surgical protocols used in this experiment have been previously published.[12] Briefly, a segmental (full-thickness) distraction gap of ~35 mm was created so that the bone was removed with its periosteal sleeve. The defect was stabilized by the reconstruction plate component of BTRP fixed with three 2.7 mm titanium screws on each side. In the experimental animals, a transport segment of approximately 1.5 cm in width was separated from the proximal mandibular stump by a bicortical osteotomy. The transport unit of the device was installed on the middle segment of the plate so that the activation screw engages the threads on the transport track. The transport unit was fixed to the transport bone segment with at least four, 1.7 mm titanium mini-screws. The activation cable was extruded posteriorly through a skin incision behind the angle of the mandible.

The animals were monitored by observation of general attitude, posture, eating, watering of the eyes, salivating, sensitivity to touch, tongue manipulation, and rubbing and pawing of the mouth. Activation of the BTRP commenced after a latency period of 5 days and progressed at a rate of 0.5 mm/12 hours (morning and evening), unless accelerated consolidation occurred, which was perceived manually as difficulty in turning the activation screw. In this case, the distraction rate was accelerated to 0.75 mm twice daily. Active bone transport distraction continued for 4 to 6 weeks until the transport segment reached the opposite edge of the defect, the docking site. This was followed by a consolidation period of 4 weeks prior to euthanasia using the protocol described before.[12] Untreated control animals were sacrificed ten weeks after surgery. The mandibles were collected for analysis, and the devices were removed.

Histological Analysis

The mandibles were resected en bloc, then sectioned into right and left halves and placed in 10% formaldehyde. Each hemi-jaw (regenerate and contralateral bone in the experimental group and untreated defect in the control group) was cut into individual blocks. The size of the blocks was approximately 35mm in length × 25mm in height × 10mm in width. The blocks were processed for undecalcified histological sections, 2-4 sections per block.

Specimens were embedded in methylmethacrylate and serial sagittal sections were prepared at a thickness varying from 100-120 μm. Sections were ground, polished to approximately 75 μm, and stained with Stevenel’s blue and Van Giesen picro-fuchsin for histological examination. The undecalcified bone samples were photographed with a digital camera (Canon Rebel XT; CanonUSA, Inc; NY) at a magnification of 1.6 X. Measurements of all the slides were taken using the NIS-Element Advanced Research®, version 2.30 (Nikon
Software, Melville, NY) that was calibrated (1 pixel = 1 μm). In both the untreated control defect and regenerate of the experimental animal slides, the amount of bone was quantified as the percent bone in the defect relative to the total area of the defect represented in each slide. In the sections of the docking site, the presence or absence of bone union was described.

Mechanical Testing

1) Specimen preparation—A line parallel to the lower border of the mandible was drawn at the level where the specimens were harvested. This line will mark the orientation of the excised disks and would be used to align them during the ultrasound experiment to identify the axis of maximum stiffness. One disk of 5 mm in diameter from each bone specimen was cut from the buccal plate near the lower border of the mandible with a trephine bur under constant irrigation with a saline solution. The specimens were stored in a 10% buffered solution of formalin in a sealed container. They were kept in this container throughout the preparation process until testing (n=5 regenerate; n=5 host). Any trabecular bone present on the specimen was removed with fine grain grinding wheel. The diameter and thickness of each specimen was measured with a digital caliper.

2) Density Measurement—The apparent density of specimens (mg/cm^3) was calculated following Archimedes’ principle of Buoyancy.[13] Each specimen was weighed suspended in distilled water. The specimens were then dried by lightly patting with absorbing paper to ensure that only the internal water remained. The specimens were then weighed again (M). These procedures were repeated three times to verify accuracy. The density of the specimens was calculated from the equation:

\[
\rho = \frac{M \rho_w}{M - S}
\]

Where \( \rho_w \) is the density of the water.

3) Ultrasonic Measurements of Material Properties—The ultrasonic velocities were measured with a pulse transmission technique described before [13-16]. In brief, longitudinal ultrasonic waves were generated by Panametrics V312-N-SU transducers (Olympus NDT, Houston, TX) resonating at 10 MHz. The transducers were powered with a Hewlett Packard Model 214A pulse generator (Hewlett Packard Palo Alto, CA). Pulse delays induced by passage of ultrasonic waves through the bone were read on a Tektronix TDS420 digitizing oscilloscope (Tektronix Texas, LLC., Richardson, TX). The bone cylinder was mounted on a 4” Rotary Table P/N 3700, (Sherline Products, Inc., Vista, CA), which allowed accurate rotations for a 360-degree turn. Ultrasonic velocities were calculated by dividing the specimen thickness or diameter by the recorded time delay minus the standard system delay. [13]. The measurement was taken in 18 different directions by rotating the specimens by 10° after each measurement.

A refined method of determining the axes of minimum and maximum stiffness in the plane of the cortical plate was used. A program written in Mathcad (version 2001, Mathsoft Engineering & Education, Inc., Cambridge, MA) was used to fit the calculated longitudinal velocities and their angular orientation for each bone specimen to a sine function \( a \sin(X + b) + c \). The coefficients \( a \), \( b \), and \( c \) corresponded to the orientation of the axes of maximum stiffness, the average velocity, and the maximum deviation of the curve from the average velocity. The direction of the axis of maximum stiffness corresponded to the direction of peak longitudinal velocity. Likewise, the minimal principal axis, or least stiffness direction, corresponded to the lowest velocity. The third axis was always tangential or perpendicular to
the cortical plane. Anisotropy was calculated by dividing minimum velocity by maximum velocity.

4) Microindentation Measurement—Material hardness is defined as its resistance to penetration by a solid body.[17] Indentation tests measure bone hardness by driving an indenter with a known geometry into a bone section. The Knoop indenter has a rhombic-shaped pyramidal diamond tip (Fig 2). Specimens were mounted in resin blocks and smoothed with carborundum paper of increasing fineness from 240-grit to 600-grit. Two vertical lines perpendicular to each other were drawn into the surface of the polished bone specimen to evenly distribute four microindentations. The mounted specimens were secured in a leveling vice of the microhardness testing machine, allowing the indenter to penetrate the specimen at a right angle. The testing mechanism was mounted to be free of vibration. Using the Knoop indenter, an indenting load of 25 grams was used with a descent time of 15 seconds. Upon reaching the lowest position, the diamond was allowed to impress the material for an additional dwell time of 10 seconds before being released. The average of the two diagonal lengths for each indentation was automatically calculated and Knoop microhardness number was provided by the formula:

$$HK = \frac{P}{A} = \frac{P}{CL^2}$$

Where $P$ is the applied load in Kg, $A$ is the projected area of indentation $(\text{mm}^2)$, $L$ is the measured length (mm) of the long diagonal, and $C$ $(0.07028)$ is a constant for the indenter relating the projected area to the square of the length of the long diagonal.[17]

Statistical Analysis

For statistical evaluation of histomorphometric data, a two sample t-test was used for comparisons between the experimental and non-treated control animals. A Kruskal Wallis test was used for testing equality of population medians among groups. The tests assumed a normally shaped and scaled distribution for each group.

Biomechanical results are displayed as Means ± Standard Deviations unless otherwise stated. A two-sample T test and a Kruskal-Wallis test were performed to evaluate the total % of bone volume formed in the defect of the two groups. Minitab 14 statistical software (Minitab, State College, PA) was used to compare thickness, diameter, hardness, and ultrasonic measurements in regenerate versus host bone using paired t-test statistical analysis. Differences were considered significant at $p<0.05$. The orientation of maximum stiffness during ultrasonic measurements was determined using the Mathcad software (Mathsoft Engineering & Education, Inc., Cambridge, MA) and assessed using circular statistical software Oriana (Kovach Computing Services, Anglesey, Wales, UK).

Results

Most dogs tolerated the surgical and post-operative procedures well, without any major complications. Soft diet and normal activities resumed immediately after surgery. Two dogs experienced loosening of the transport device screw and underwent a surgical procedure to correct it. One animal was excluded from the study due to complications of wound dehiscence. The remaining lengthening period occurred without significant incident.

Histological and histomorphometric Evaluation

Tissues from one animal in the untreated control group were excluded because the edges of the defect could not be identified. Control animals showed no sign of bone regeneration.
across the surgical defect. The defect contained mostly fibrous tissue in the middle of the defect with very small areas of regenerate bone formed from the edges of the host bone into the defect. This small amount of calcified tissue appeared woven and lacked evidence of maturation (Fig 3A, B).

All the animals in the experimental group showed remarkable bone regeneration across the surgical defect. Bone formed from the host bone towards the transport disc, and from the transport disc back to the host bone, producing less well-developed bone in the center of the defect and thicker bone at the outer edges of the defect (Fig 3C, D). The bone volume fraction in the repaired defect was 43% in the experimental animals, as opposed to 6% in the untreated control group (p < 0.01; Fig 4).

Half the dogs showed non-union at the docking site. Histological sections from the docking sites in all animals showed that the transport disc produced a cone-shaped outgrowth of new bone into the anterior portion of the defect. The recipient bone segment also produced a conical outgrowth of new bone into the defect. As the transport segment approached, these cone-shaped bone outgrowths prevented the transport disc from having proper apposition with the host bone, giving the docking site an hourglass outline. In dogs where non-union was observed, this pattern was associated with fibrous tissue interposition between the transport disc and the opposite segment of the defect, preventing any contact between the transport disc and the recipient mandibular bone segment (Fig 3E, F).

**Physical Properties**

Specimens prepared for mechanical testing were comparable in physical dimensions between the regenerate and contralateral sides. The regenerate specimens had a mean diameter of 4.91 ± 0.08 mm; while the contralateral specimens had a mean diameter of 4.77 ± 0.23 mm (p > 0.05). Regarding thickness, the contralateral samples had a mean thickness of 2.01 ± 0.40 mm while the regenerate group had a mean thickness of 2.13 ± 0.32 mm. Differences in physical dimensions were not statistically significant (Table 1).

The regenerate samples had a mean density of 1513 ± 171.7 kg/m³ while the contralateral samples had a mean density of 1947 ± 68.8 kg/m³, a 22.3% statistically significant difference between the two groups (Table 1). The regenerate samples had a mean microhardness of 14.8 ± 2.0 kg/mm² that was statistically significantly lower than the contralateral samples with a mean microhardness of 25.8 ± 5.4 kg/ mm² (Table 1).

The correlation coefficient (rr) values were statistically significantly lower for the regenerate samples (0.62 ± 0.29) than for the contralateral samples (0.93 ± 0.09) (Table 2). The angle of maximum stiffness was not significantly different between the two groups (regenerate 33.3 ± 46.7; contralateral 21.4 ± 35.3) (Table 2), and coincided with a plane parallel to the lower border of the mandible. The maximum velocity (representing the maximum stiffness) was statistically significantly higher for the contralateral samples (3.98 ± 0.22) when compared to the regenerate group (3.3 ± 0.24) (Table 2). The minimum velocity (representing the minimum stiffness) did not show any statistically significant differences between groups (contralateral 3.09 ± 0.37; regenerate 3.04 ± 0.12) (Table 2). The anisotropy (representing difference in bone tissue orientation in different planes, a parameter of bone maturation) of the regenerate specimens (0.92 ± 0.06) was statistically significantly less than that of the contralateral group (0.77 ± 0.07) (Table 2).

To determine correlations between microhardness and density and between anisotropy and density, paired t test showed a linear correlation between density and both microhardness and anisotropy. With an increase in density, an increase in microhardness (Fig 5A) and a more significant anisotropy was observed (Fig 5B).
Discussion

In this study, we tested a new device called bone transport reconstruction plate (BTRP) in reconstruction of mandibular segmental defects. The device proved to be easy to install, activate, and adjust. It was well tolerated by most animals. The advantage of BTRP is that it utilizes the middle segment of the reconstruction plate as the transport track. Therefore, the transport follows the contour of the original mandibular outline and was stable throughout the process. Success of the linear version of this device opens the way to testing the next phase, which is carrying the transport disc across the midline via a curvilinear vector. Since the transport unit is small in size and is carried on the plate itself, it should be easy to delay the distraction process or divide it into stages if needed, a unique advantage over previous devices.

Bone regeneration by BTRP was successful, creating 43% fill of the defect after 1 month. Previous histological studies examining bone regenerate of BTDO produced similar results at a later time point, 8 weeks of consolidation.[18-20] Zhao and co-workers reported that after 8 weeks of consolidation, the regenerated bone showed very thin bone trabeculae parallel to the distraction vector and also there were signs of lamellar ossification. [25] It wasn't until the 12th week of consolidation that the regenerate bone was thicker than the host bone, and a more mature lamellar ossification was observed.[21]

Reconstruction of mandibular defects aims to restore normal jaw functions while maintaining acceptable facial esthetics. Functional reconstruction requires building new bone within the defect with sufficient alveolar height and thickness and optimal architectural quality. This would allow for permanent restoration of dentition, maxillo-mandibular occlusion, mandibular continuity, and rehabilitation of jaw functions, such as mastication, deglutition, sensibility of the mucosa, tongue movements, lip competence, and speech. At the same time, esthetic reconstruction requires the restoration of normal appearance of the soft-tissues, facial symmetry, dental arch, and lower facial dimensions.[22-24]

Extraoral bone transport devices have the advantage of fast application, minimal interference with the soft tissues, which is a major advantage whenever soft tissue flaps are used, and easy troubleshooting. However, these devices provide little torque to drive the transport disc against significant soft tissue resistance. Likewise, they provide minimal support to the transport disc against the tension forces of the soft tissue, resulting in significant inward displacement of the regenerate.[2]

Intraoral bone transport devices, on the other hand, provide better stability to the bone segments, since they all depend on reconstruction plates to stabilize the mandible. However, available devices are bulky and difficult to install and troubleshoot. Most importantly, these devices are limited by design to unilateral defects.[25]

Other investigators performed transport distraction in dogs in a smaller (20 mm) defect, allowing a period of 90 days for consolidation. Under their protocol, they achieved complete bone regeneration, meaning that the regenerated segment was similar in density and histologically when compared to the rest of the mandible.[10]

It is essential to validate the size of the defect to be large enough to be called a critical size defect whenever an animal model is used. The critical size for segmental defects in the dog mandible depends on the size and age of the animal, the preservation or excision of periosteum around the defect, rigidity of fixation, viability of the tissues around the defect, and the incidence of local complications after resection. Other factors may also play a role in determining the generalized healing status of the animal, such as nutrition, physical activity, and general condition of the animal. Because of all these variables, it was important to
include a control group of the same size and living conditions to validate this critical-size defect model. Huh and co-investigators suggested that a 15 mm defect with excision of periosteum would not spontaneously heal during the dog's natural life.\textsuperscript{26} Other authors suggest larger defects (30 mm).\textsuperscript{27} In this model, we demonstrated that a 34 mm segmental mandibular defect with excision of overlying periosteum will not heal spontaneously in dogs under our study conditions.

We have previously shown that the physical dimensions of the regenerate at this time point were comparable to those of the contralateral bone, an important requirement for implant placement.\textsuperscript{12} However, differences in density and microhardness values between the regenerate and contralateral bone presented in this study suggest that this time point would probably be too early for implant placement. Further studies are underway to determine the time point most suitable for implant placement in the regenerate and transport disc.

Although radiographic and histological analyses of distracted bone are plentiful, few studies have examined its mechanical properties. In addition, the methodology used in various studies was highly variable, making results difficult to compare. Despite these differences, some studies showed that the regenerate bone's mechanical properties were lower when compared to host bone,\textsuperscript{28-37} supporting our microhardness results. However, one important issue of previous studies was the assumption that cortical bone can be modeled as an isotropic material, which is partially supported by one report\textsuperscript{38} but contested by others.\textsuperscript{16, 39, 40} The present study attempts to evaluate the regenerate bone at the microstructural level (osteons and Haversian system) through microindentation testing, eliminating errors associated with whole-bone evaluations and to assess the anisotropic characteristic of bone by use of ultrasonic longitudinal velocities.

The axis of highest velocity represents the axis of maximum stiffness, as ultrasound passes more rapidly as stiffness increases. Axis of minimum stiffness corresponds to the axis of lowest velocity.\textsuperscript{16} In the experimental group, the contralateral side showed higher maximum velocities as well as hardness than the regenerate.

The orientation at maximum longitudinal ultrasonic velocity was, in most specimens, close to the plane parallel to the lower border of the mandible for both the regenerate and contralateral bone. This is similar to a previous study that showed that the inferior corpus of the human mandible had the least variation in the direction of maximum stiffness and is typically parallel to the lower border of the mandible.\textsuperscript{40}

Degree of anisotropy was calculated using maximum and minimum velocities of longitudinal ultrasonic waves. The significantly less anisotropy observed in the regenerate group suggests less organization of bone in these specimens at 4 weeks of consolidation. A previous study reported the formation of immature woven bone with extracellular matrix relatively organized at 4 weeks of consolidation.\textsuperscript{41} On the other hand, another study described that during distraction-induced callus formation, collagen fibers are aligned parallel to the vector of distraction, suggesting that the subsequent mineralization would be in the same orientation of the distraction vector.\textsuperscript{42} This, however, would relate more to the orientation of the early trabecular bone. At 4 weeks of consolidation, cortical condensation starts, from which the examined discs were harvested. The ultrasound data would, therefore, relate to the orientation of collagen fibers within the cortex and not the gross orientation of trabecular bone within the whole regenerate.

Hardness is the resistance of a material to penetration\textsuperscript{43, 44}, while stiffness relates to the amount of deformation of a material relative to the load applied to it.\textsuperscript{16} In the present study, hardness was chosen to characterize the regenerate bone at the microscopic level. Specimens were preserved in formalin, which has unknown effects on the hardness of bone.
However, since both the regenerate and contralateral bone samples underwent the same fixation protocols and duration, comparisons should not be influenced by the method of fixation.

Alternative testing methods for bone mechanical properties include the compression/tension loading,[28] strain gauge measurement of bone stiffness,[29] three-point bending,[47][31] cantilever-bending,[30] and four-point bending.[33] In the current study, we examined the bone at a relatively early time point (one month of consolidation). Therefore, whole-bone mechanical tests would be inappropriate, since they do not account for anisotropic and inhomogeneous properties of the regenerate at this stage.[13, 48]

Bone transport distraction osteogenesis (BTDO) has proven to be very successful in the reconstruction of segmental mandibular defects, and in the generation of new bone in studies performed in animal models and in human patients.[4, 7, 49-51] Compared to other methods of mandibular reconstruction, including bone grafts, whether vascularized or non-vascularized, allogeneic materials, or guided-bone regeneration, BTDO offers the advantage of creating new bone that has the same physical dimensions and tissue properties as the host bone. Additionally, BTDO eliminates donor site morbidity and reduces the length of the surgical procedure.[10]

The most challenging aspect of transport distraction osteogenesis remains to be the achievement of union at the docking site. Non-union was evident in half our animals. Some techniques were developed clinically to achieve union at the docking site including sustained compression, alternate compression-distraction, bone grafting, and adjunctive therapies such as electromagnetic stimulation, low intensity ultrasound, and bone-inducing factors.[52], [53]

For the success of these techniques, it is very important that the transport disc maintains an adequate blood supply. This is important for bone union at the docking site and for a more rapid consolidation.[54, 55] Also, the transport disc must remain stable and attached to the transport unit, and must have adequate apposition with the distal native bone stump. The distraction device must also have the mechanical properties to hold the transport segment firmly at the docking site, and preferably be able to apply sustained compression at after docking.[8] Two more issues interfere with healing at the docking site, first is the growth of bone spikes from the recipient bone segment that prevent the advancement of the transport segment all the way to the docking site. Second is the interposition of soft tissues in between the advancing edge of the transport disc and the recipient bone segment. Both of these issues were encountered within our experimental group.

Conclusions

It is possible to reconstruct segmental mandibular defect using BTRP. At 4 weeks of consolidation, all experimental defects showed successful defect bridging, with 46% of bone volume restored within the defect and 50% of union achieved at the docking site. At this time point, the regenerate bone has not yet achieved full mechanical integrity, evident by lower density, lower microhardness values, and less significant anisotropy values when compared to the host bone. The device proved stable and easy to use and the results are promising for reconstruction of large mandibular defects. More studies are underway to test the appropriate conditions for implant placement, the possibility of reconstructing bone across the midline, and methods to improve healing at the docking site.
